Executive Summary

U.S. growers harvested 125.3 million pounds of fresh asparagus in 1993, with a total crop value reported at \$163 million. Asparagus is grown in most temperate areas of the U.S., although the majority of commercial production is located in California, Washington, and Michigan. Other commercial growing areas include Illinois, Indiana, Maryland, Minnesota, New Jersey, and Oregon.

About 57 percent of U.S. asparagus production was destined for fresh-market use in 1993. Virtually all of the asparagus grown in California is sold for the fresh market, and a portion of Michigan and Washington output is sold to the fresh market. Output in the minor production areas is sold almost exclusively for fresh-market use.

Fresh-market asparagus prices demonstrate a very pronounced seasonal pattern. They are highest at the beginning of the season (January-March) and at the end of the season (August-September) when shipment volume is smallest. During the high-price periods, southern California (the Imperial Valley) is the principal shipper. Fresh-market prices are generally lowest in mid-season (April-May) when shipment volume is greatest and harvest is peaking in central California, Washington, Michigan, and other states.

Income diversification--from off-farm employment and crop diversification-enhances the ability of asparagus growers to manage risk. According to the Census, over half of the 3,033 farms with asparagus sales in 1987 reported the operator working off the farm at least one day, and 30 percent reported the operator working off-farm 200 days or more. Further, asparagus growers appear generally well-diversified with other crops.

Asparagus is a perennial crop that has a life expectancy of up to 30 years, although the life of most commercial plantings is less than 20 years. An asparagus bed produces a small crop one year after crowns (the underground part of the plant) are transplanted. However, a bed is only partially productive the first three years after transplanting. Commercial fields receiving average care yield their largest output at 5 to 7 years of age in California. Plantings in Michigan reportedly produce their maximum yields at 5 to 12 years of age. Beyond that time, yields tend to decline.

The crop cycle for established asparagus consists of: 1) a 4-8 week harvest in the spring and early summer, 2) a summer fern growth (or re-establishment) period during which the plant re-stocks its energy reserves in the roots and crown, and 3) a rest period brought on by cold weather or drought.

In the spring, spear growth occurs when soil temperatures reach 50° F. Daily average temperature affects the rate of growth of the spears. For example, the asparagus shoot requires 5 days to produce a 6-inch spear with daily average temperatures of 53° F. In contrast, at 78° F, a shoot will reach 6 inches in about 1.9 days. Although spears grow faster at higher temperatures, extremely high temperatures also promote early branching of the shoot. Late spring frost is the most common weather-caused peril reported in all major production areas. Asparagus is one of the first plants that emerges in the spring, with harvest beginning as soon as spears reach marketable length. As a result, asparagus is quite vulnerable to frosts. Frost damages or kills any spears that have emerged from the soil, making them worthless, and slows the development of new spears.

Other perils include extended cool weather, excess heat, excess moisture, hail, insects, and diseases. These perils can reduce the current year's production during the harvest season. They can also reduce fern growth during the re-establishment period, and thus, diminish yields in subsequent production years. Asparagus is fairly drought-tolerant, with roots that can reach a depth of 15-20 feet in sandy soils.

The multi-year effect of natural perils on yields, as described above, has implications for the offering of an asparagus crop insurance policy. In order to avoid adverse selection--growers taking out insurance after an event occurred that reduced future yield prospects--it may be necessary to require that growers insure for a period of years. A minimum step in reducing adverse selection would be to define the crop year as beginning with fern growth in one year, extending through the conclusion of harvest the following year.

Other insurance issues addressed in this report include: setting reference prices, estimating "appraised production," and the demand for insurance. One key issue is determination of the actual production history calculation, as expected yield varies with the maturity of the asparagus bed.

Our assessment is that asparagus is not as good a candidate for insurance as the previous specialty crops we have examined. The insurance issues noted above make policy development difficult, but not insurmountable. Further, there are questions concerning the potential demand for an asparagus policy. The largest demand is likely to occur in Michigan and other midwestern and eastern areas because weather-related losses appear to be more frequent in these areas than in California and Washington. However, even in these areas, it is questionable as to how often a grower would experience a loss of the 25percent or more that would be required to collect an indemnity.

Ad hoc disaster assistance data can be used to provide a further indication of areas of expected high losses, as well as the demand for insurance. Michigan and Illinois collected a relatively large share of ad hoc disaster payments for asparagus relative to their acreage. However, overall, ad hoc disaster assistance payments to asparagus growers in the nine USDA-reported states amounted to only 0.2 percent of the value of crop, compared to 2.4 to 6.6 percent for major field crops.

Asparagus: An Economic Assessment of the Feasibility of Providing Multiple-Peril Crop Insurance

Introduction

Asparagus is an herbaceous perennial, valued for the succulent shoots (spears) which are used fresh, canned, and frozen. It has been grown in American gardens since the earliest settlements were established. Commercial plantings were first made about 1860 (Ehlert and Seelig).

Asparagus is grown in most temperate areas of the United States, although the majority of commercial production is located in California, Washington, and Michigan (Table 1). Other commercial growing areas are located in Illinois, Indiana, Maryland, Minnesota, New Jersey, and Oregon. The 1987 Census of Agriculture reported asparagus acreage in 38 states. In 1993, the reported value of the U.S. asparagus crop was \$163 million (USDA, NASS).

This report examines those aspects of the asparagus industry that relate to the demand for crop insurance and the feasibility of developing an asparagus insurance policy.

The Asparagus Market

Supply

U.S. fresh asparagus production peaked in the late 1980's, and has declined slightly since that time (Table 2). The 1993 fresh asparagus crop is estimated at 125.3 million pounds, down about 16 percent from the 1989 peak. The amount of total production going for the fresh market (57 percent of the 1993 crop) is far larger than that destined for canning (32 percent) and freezing (11 percent). (See Tables 2, 3, and 4).

Imports account for a significant, and an increasing, share of the total U.S. supply of asparagus. Imports of fresh asparagus rose from 32 million pounds in 1988 to nearly 70 million pounds in 1993, and imports of frozen asparagus rose from about 1 million to about 5 million pounds. Canned asparagus imports have declined, however, from about 7 million pounds to 4 million. In 1993, 24 percent of total U.S. asparagus supplies were imported, mostly from Mexico.

The United States also exports a substantial amount of fresh asparagus, and a small amount of canned asparagus. In 1993, the United States exported 23 percent of its asparagus production, mostly fresh product to Canada, Japan, and Europe.

The domestic harvest of fresh-market asparagus begins with small volumes from southern California during December and January. Supplies increase as the season extends north to central California during February and March, peaking during April and May when central California, Washington, Michigan, and other

states are harvesting. Shipments decline during June and the season ends in early July A small amount of fresh-market asparagus is harvested in central and southern Californi during the summer and fall.

Demand

Asparagus accounts for only about one-quarter of one percent of U.S. total vegetable consumption, which includes potatoes, sweetpotatoes, mushrooms, and dry beans and peas (USDA, ERS). Per capita use of asparagus (in all its forms) has been virtually unchanged over the past 20 years, at around 1.0 pound.

Asparagus is used in its fresh form and is also canned and frozen. It can be served in salads, soups, hot dishes, and in combination with various sauces. The whole spears ma be served or they may be cut into pieces.

A seasonal peak in fresh use occurs during the spring. This is a result of its ready availability during that period, and relative scarcity during other periods, rather tha any shift in consumer demand.

Unlike a number of other perishable vegetables, the quantity of asparagus demanded appears to change quite easily when its price changes. A given change in price, for example, is associated with a more than proportional opposite change in the quantity demanded. Conversely, a smaller-than-proportional change in price is associated with a given change in quantity supplied.

This characteristic is referred to as an elastic demand. One statistical study estimated that a 1-percent increase in per capita quantity of fresh asparagus is associated with a 0.36 percent decrease in the grower price (French and Willett).

Prices

Fresh-market asparagus prices demonstrate a very pronounced seasonal pattern. They are highest at the beginning of the season (January-March) and at the end of the season (August-September) when shipment volume is smallest. During the high-price periods, southern California (the Imperial Valley) is the principal shipper. Fresh-market price are generally lowest in mid-season (April-May) when shipment volume is greatest (Table 5). These lower prices correspond with the peak harvest period in central California, Washington, Michigan, and other states.

The low prices during October of 1992 and 1993 probably reflect the effects of a glut o fresh asparagus in specialty markets due to increased production from the Imperial Valley and rising imports. The demand for fresh asparagus outside the high-volume spring season is as an out-of-season item largely in specialty stores. Mini-supply peaks during October of 1992 and 1993 flooded this specialty market and resulted in unusually low prices.

Table 5--Asparagus: U.S. f.o.b. prices, monthly averages, 1989-93

Source: Computed from USDA, NASS.

Although there may be rather large year-to-year variations in prices at the beginning and end of the season, prices during mid-season are relatively consistent across years. Mid-season prices are closely tied to the price for processing asparagus. If freshmarket and processing prices diverge very far during harvest in Washington and Michigan (the principal processing states), asparagus is diverted from fresh to processing use, thereby maintaining the prices for the two uses in close alignment. Prices for a large portion of processing asparagus production are negotiated prior to the beginning of the season and do not change very much from year to year.

Industry Characteristics

Some of the more salient aspects of the asparagus industry which have significance in assessing the demand for crop insurance include:

- ! A relatively large proportion of farm operators producing asparagus who depend on farming for their principal source of income,
- ! Widespread use of irrigation in California and Washington, which reduces drought risks in those areas, but limited irrigation use in Michigan and other eastern states, and
- ! Substantial diversification in the enterprise mixes on asparagus farms that spreads income risk over several crops.

The primary sources of available information on farms producing asparagus are the 1987 Census of Agriculture and USDA's 1992 Vegetable Chemical Use Survey.¹

Asparagus Farms

The Census of Agriculture reported 3,033 farms with sales of asparagus in 1987 (Appendi table 1). The largest number of farms and the majority of the acreage were in California, Washington, and Michigan. The Census also reported 1,000 acres or more of asparagus in Arizona, Minnesota, New Jersey, and Oregon. USDA reports asparagus statistics for all of the above states, except Arizona (see Table 1).

The majority of farms growing asparagus in California in 1987 were relatively large operations: 52 percent had sales (from all crops) of \$500,000 or more and 74 percent had sales above \$100,000 (Appendix table 2). In Washington, 11 percent of farms with asparagus sales reported having total crop sales of \$500,000 or more and 48 percent had sales greater than \$100,000. In contrast, Michigan farms with asparagus were substantially smaller in terms of crop sales than those in California and Washington. Only 2 percent of Michigan farms with asparagus had total sales of \$500,000 or more in 1987, while 75 percent had sales of less than \$50,000.

 $^{^{1}}$ Results for the 1992 Census of Agriculture were not available for all states at the time this report was prepared.

In terms of organizational structure, individual or family ownership was the most frequent type of arrangement among farms with asparagus in Michigan and Washington in 1987, while partnerships and corporate arrangements were more common in California (Appendix table 3). Partnerships and corporate arrangements (either family held or other) were more typical among the larger farms than among the smaller ones. One hundred and sixty of the 209 farms with sales of \$500,000 or more reported a partnershi or corporate-type organizational structure.

Income Diversification on Asparagus Farms

Income diversification enhances producers' ability to manage risk. Sources of income diversification on asparagus farms include: 1) diversification with off-farm employment, and 2) diversification of receipts from asparagus with other farm enterprises.

Off-farm income is a more important source of diversification for small farms than for larger farms. Sixty-four percent of all farm operators growing asparagus in 1987 reported that farming was their main occupation (Appendix table 4). Over half of the farms, however, reported the operator working off the farm at least one day in 1987 and about 30 percent reported the operator working off the farm 200 days or more. Most of those operators working off the farm 200 days or more were from farms with total sales of less than \$25,000.

Market sales for asparagus growers are substantially diversified between asparagus and other crops. Of the \$614 million in market sales reported by the Census for farms growing asparagus in 1987, \$310 million were sales from vegetable crops including asparagus (Table 6). The USDA's Crop Reporting Board estimated the value of asparagus production at \$136 million in 1987, which is about 22 percent of total sales reported b the Census for farms with asparagus.² The greatest specialization occurred in Washington, where asparagus accounted for 36 percent of total farm sales on farms producing asparagus.

Vegetable acreage reported by growers in a 1992 survey of chemical use in 10 states indicates that asparagus accounted for a relatively large share of their total vegetabl acreage, particularly in Michigan and Washington. In those states, asparagus accounted for 60 and 66 percent, respectively, of total vegetable acreage on farms growing asparagus (Table 7).³

The chemical use survey also provides information on the crops grown on farms producing asparagus. Fresh sweet corn and fresh tomatoes are insurable

² Although Crop Reporting Board asparagus data do not include all states reported by the 1987 Census, its coverage includes states that accounted for 94 percent of 1987 Census acreage.

³ The survey included vegetable farms in Arizona, California, Florida, Georgia, Illinois, Michigan, New Jersey, New York, North Carolina, and Texas.

specialty crops that were produced on farms growing asparagus (Table 8). The Oregon an Washington farms sampled were less likely to produce currently-insurable specialty crop than in the other asparagus-producing states.

Cultivation and Management Practices

Asparagus is a perennial crop belonging to the plant group called Liliacaea. The asparagus plant has a relatively long life expectancy ranging up to 30 years, although the life of most commercial plantings is less than 20 years. The life of an asparagus bed (or plantation) depends on natural conditions and the care given to the bed.

An asparagus bed produces a crop one year after the crowns (see below) are transplanted However, it is only partially productive for the first three years after transplanting. A bed generally produces about 10 percent of its maximum yield in the second year (the year after transplanting), about 50 percent in the third year, and 80 percent in the fourth year. Commercial fields receiving average care yield their largest output at 5 to 7 years of age in California (California Asparagus Commission). Asparagus plantings in Michigan reportedly produce their maximum yields at 5 to 12 years of age (Foster).

The crop cycle for established asparagus consists of: 1) a 4-8 week harvest in the spring and early summer, 2) a summer fern growth (or re-establishment) period during which the plant re-stocks its energy reserves in the roots and crown, and 3) a rest period brought on by cold weather or drought.

Virtually all the asparagus grown in the United States is classed as green asparagus. White (blanched) asparagus production is common in Asia and Europe. Fresh white asparagus, however, is rare in U.S. markets. White asparagus is produced by avoiding exposure of the young spears to light. The traditional method for excluding light is t mound the soil over the plant row to an 8- to 10-inch height. Once the tip of the soil mound starts to crack, an asparagus knife is thrust into the mound, cutting off the spear before it is exposed to light. Otherwise, culture and pest control are similar t green asparagus.

Climate

Asparagus is a native of temperate regions and cultivation is most successful where either low temperatures or drought stop growth of the plant, providing it with a rest period. Areas with monthly average temperatures of $60^{\circ}-75^{\circ}$ F and a winter dormant peric produce the best crops. Asparagus is not grown successfully in the South, where extrem heat and plentiful rainfall permit the continuation of shoot growth late in the season, thereby depriving the plant of the dormant period needed for successful production the subsequent year. Successful crops are produced in warm, irrigated areas, including the Imperial Valley of California, where irrigation water is withheld to slow vegetative growth and provide a rest period.

Table 8--Insurable crops on farms producing asparagus, 1992

Source: USDA, Vegetable Chemical Use Survey, 1992.

Spear growth occurs when soil temperatures reach 50° F (Sims, et. al.). Daily average temperature affects the rate of growth of the spears. For example, the asparagus shoot requires 5 days to produce a 6-inch spear with daily average temperatures of 53° F. In contrast, at 78° F, a shoot will reach 6 inches in about 1.9 days. Although spears grow faster at higher temperatures, extremely high temperatures also promote early branching of the shoot. Shoots at 100° F branch at 2 to 3 inches above the ground, while at 59° F they branch at 30 to 40 inches. Early branching is an undesirable characteristic.

Soil Requirements

Asparagus grows best in deep, well-drained, loamy sand, sandy loam, or loam soils. Heavy clay soils which drain slowly and are difficult to penetrate may result in a larg percentage of poor spears and relatively short-lived beds. Sandy soils produce earlier crops because they warm faster in the spring. A slightly acid soil with a pH of 6.0-6. is preferred for asparagus production.

Asparagus is relatively salt-tolerant. Consequently, it is grown successfully in deser areas of California where the salt level of the soil is quite high.

Varieties

The asparagus industry is undergoing a major change, from the planting of openpollinated varieties (such as Mary Washington, Martha Washington, and Viking KB3) to th planting of hybrid varieties with enhanced yield potential. A number of the new hybrid varieties consist of all-male or nearly all-male plants that have evolved from research at Rutgers University in New Brunswick, New Jersey. Some of these recommended hybrids include Jersey Giant, Jersey Price, Jersey King, Jersey Knight, Jersey Gem, and others.

The primary asparagus variety in California is the hybrid UC 157. Other California varieties include UC 72, the 800 series, Brock's Special, and Ida-Lea (Sims, et. al.). UC 157, released in the fall of 1975 for commercial use, exhibits earliness in production, multi-spear initiation, uniformity in color and size, and greater total production than other varieties (University of California, 1977). Brock's Special was developed for the hot, desert growing conditions of the Imperial Valley.

All-male hybrids produce only male plants and thus produce no seeds. As a result, food that goes into fruit production in dioecious varieties is stored in the roots of allmale varieties and provides added vigor for spear production the following spring. Tes results in Washington and Michigan indicate that the all-male hybrids may produce doubl the yields of standard cultivars such as Mary Washington (Dean). Another advantage of all-male hybrids is that no problems with seedling asparagus occur in established field because the plants produce no seeds (Zandstra, Dean).

Planting

Asparagus is established in the field by transplanting 1-year-old crowns (the underground portions of the plant). Crowns are grown from seed planted in nursery beds Growers may produce their own crowns or purchase them from nurseries specializing in crown production. Although asparagus can be seed-planted in the field, the use of 1-year-old crowns results in a more uniform stand and reduces the time from planting to the first harvest. Once established, an asparagus planting may be harvested for 12 to 15 years, or longer.

Asparagus crowns are transplanted in most growing areas from early spring through midsummer, depending on climate conditions. In California, transplanting is done from February through April in the desert regions, from March through May in the lower San Joaquin Valley and the Delta, and from April through July in the cooler coastal areas (Sims, et. al.).

Asparagus crowns are transplanted 6 to 12 inches apart in rows that are 4 to 5 feet apart. Crowns are covered with only 2-3 inches of soil at planting time. They are planted in 8-10 inch deep farrows. As the young plants grow, the farrows are filled in during the first growing season until the field is level.

Weed control is especially important in newly-planted asparagus because the young plant grow slowly and compete poorly with weeds. Failure to control weeds adequately during establishment may permanently reduce the vigor of the stand. Cultivation and herbicide are used in weed control. Weed control is more difficult in new plantings than in established beds because young asparagus plants are more sensitive to herbicides and cultivation.

Fertilization

Asparagus has relatively high fertilizer requirements during the establishment period because the developing crown and root storage system have large nutrient requirements. Less fertilization is needed after the first two or three seasons than during the establishment period because nutrient removal in the harvested spears is relatively low (Dean).

Irrigation

Asparagus is a fairly drought-tolerant crop because of its deep and extensive root system and, therefore, is not a heavily irrigated crop. Nevertheless, its roots should not be deprived of moisture for long periods during the growing period. Virtually all of the asparagus in California and Washington is irrigated (see Appendix table 1). A small percent of asparagus production in Michigan is irrigated. Irrigation promotes fern top growth in asparagus and increases the buildup of energy for the subsequent crop.

Harvesting

Asparagus cannot be harvested during the year that the crowns are planted because the plants must be allowed to grow and develop a strong storage root system. Sometimes, growers may harvest five or six times during the year following transplanting if the plants are particularly vigorous. Good vigor is essential for second-year harvesting, however, because harvesting too soon stresses the plant and reduces future yields. The Michigan Agricultural Extension Service recommends waiting until the third year to star harvesting.

Asparagus harvesting (cutting) in California and Washington is done with a special knif which cuts the young spears just below the soil surface. In Michigan, asparagus is "snapped off" by hand without the use of a knife. Hand snapping may be faster and less costly than cutting, but it also may result in less uniformity in the cut spears. Michigan's asparagus is processed primarily as "cuts and tips" where uniformity of the spears is less important than in situations where the final product is in whole-spear form. Washington asparagus is processed primarily as whole spears.

Asparagus spears grow rapidly and require frequent cutting, especially if the temperature is high. Early in the season, the shoots may require cutting only every third day, but as the growth becomes more active it may be necessary to cut twice a day especially if the asparagus is growing on very light, warm soil. A typical harvesting schedule consists of cutting 2 or 3 times a week, for about a 6-8 week period.

Harvesting ends early enough to allow an extended season for fern growth. During the fern growth (or re-establishment) period, plants accumulate food reserves for the next cutting season. Cutting may be stopped before the latest recommended harvesting date i there is an appreciable reduction in spear diameter. Table 9 shows typical harvesting dates for asparagus, by state, as reported by USDA.

Packing and Shipping Fresh Asparagus

Asparagus is one of the most perishable vegetable crops. Thus, proper cooling is essential in the storage and shipping stages to avoid weight loss and reduced quality. If cooling does not occur quickly, asparagus loses natural sugars and some of its flavor. In addition, spears can become tough due to the formation of woody tissue, and decay is more likely to develop. Asparagus is usually maintained at a temperature between 34° F and 37° F and a relative humidity of 90 to 95 percent during storage and shipping. If rapidly cooled and held under such conditions, asparagus may be kept for maximum of 3 weeks.

There are generally two types of packaging for fresh asparagus--bunch pack and loose pack. Bunch packs consist of various different bunch weights, spear sizes, and crate weights. In contrast, loose-packed spears are trimmed to the desired length (usually eight or nine inches) and placed in a crate, each of which contains 30-32 pounds. In California, as much as 80 percent of the state's production is packed out loose in 30-pound crates (University of California, 1993).

Stalk size is designated according to the diameter, measured at the widest portion of the spear. Sizes include Jumbo--13/16-inch and larger; Large--

Marketing

About 57 percent of U.S. asparagus production was destined for fresh-market use in 1993 (USDA, NASS). Virtually all of the asparagus grown in California is sold for the fresh market, and a portion of Michigan and Washington output is sold to the fresh market. Output in the minor production areas is sold almost exclusively for fresh-market use.

Although producers in Michigan and Washington sell most of their asparagus for processing use, when fresh-market prices rise sufficiently, they divert some asparagus from processing use to fresh use. Consequently, during the main harvesting season, fresh and processing asparagus prices maintain a relationship roughly equivalent to the additional costs for packing and selling fresh-market asparagus.

Grower bargaining associations negotiate prices for processing asparagus in Washington and Michigan. In Washington, the Washington-Oregon Asparagus Growers Association is th growers' bargaining agent. In Michigan, the grower bargaining agent is the Asparagus Growers Division of the Michigan Agricultural Commodities Marketing Act (MACMA). MACMA represents roughly 85 percent of the volume of processing asparagus in Michigan and the negotiated price effectively becomes the industry price that season. Similarly, in Washington, the association price effectively becomes the industry price even though on large processor, Green Giant, does not purchase its asparagus through the association.

There are no Federal marketing orders for asparagus. California, Michigan, and Washington have state asparagus commissions which fund promotion, as well as production and marketing research, with grower assessments based on the amount of production. The commissions also support foreign market development and promotion through "Asparagus USA". Asparagus USA is a consortium of the California, Michigan, and Washington asparagus commissions, which administer the program on a rotational basis.

Costs of Production

Variable harvesting and marketing expenses account for a substantially larger share of total costs in fresh-market asparagus production than in processing asparagus production. Estimated harvesting and marketing expenses accounted for nearly threequarters of the total costs of producing fresh-market asparagus in Imperial County, California in 1993 (Table 10).⁴ Because marketing expenses for processing asparagus are substantially lower than for fresh-market asparagus (processing asparagus has minimal packing and selling

⁴ Detailed cost of production budgets are presented in Appendix table 6.

Table 10--Asparagus: Variable harvesting costs, selected states $^{1 \ /}$

State	Yield	Variable harvest cost	Total cost	Variable harvest percent of total
	Pounds/acre	\$/acre	9	Percent
Imperial county, California	4,500	3,000	4,082	73
Michigan	1,400	276	1,057	26
Washington	4,000	1,019	2,184	47

^{1/} Costs may not be comparable among states because budgets may be for different seasons and may not include the same cost items. Costs for California are for fresh asparagus production in Imperial County. Costs for Michigan and Washington are for processing asparagus.

Sources: Joshua, et. al., 1994; Kelsey, 1989; University of California, 1993.

expenses), the variable costs of harvesting constitute a substantially smaller share of total costs for processing asparagus than for fresh-market. Harvesting expenses for processing asparagus account for about one-quarter of total costs in Michigan and about one-half in Washington.

As with other fresh vegetables, variable harvesting and marketing expenses for asparagu play a role in growers' decisions about when to stop harvesting which could, consequently, have an effect on annual yield. If the asparagus price falls below harvesting and marketing expenses and the end of the harvest season is approaching, growers may stop cutting sooner and yields would be lower than if prices were higher. On the other hand, if prices are relatively high as the end of the season approaches, growers may try to extend harvesting to take advantage of the higher price.

Growers have limited flexibility, however, in altering yields by adjusting the number o cuttings. They may be reluctant to stop cutting early because if prices subsequently rise, they can not resume harvesting and take advantage of the higher prices. On the other hand, growers are reluctant to extend the harvest by very many cuttings because o the possibility of jeopardizing the vigor of the bed and lowering yields in future seasons.

Production Perils

The greatest peril to asparagus production is frost or freeze damage during the harvest season that kills the spears, making that portion of the crop unmarketable. Other perils include extended cool weather during the harvest season, excessive heat during the harvest season, excessive moisture, hail, insects, and diseases. Of course, perils can reduce the current year's production during the harvest season. In addition, peril can also reduce fern growth during the re-establishment period, and thus, diminish production in subsequent years.

Frosts and Freezes

Late spring frost is the most common weather-caused peril reported in all major production areas. Asparagus is one of the first plants to emerge in the spring, with harvest beginning as soon as spears reach marketable length. As a result, asparagus is quite vulnerable to frosts. Frosts are more prone to occur early in the harvest period when yield per cutting is usually highest and the damage in terms of reduced yield, consequently, is greatest.

Frost damages or kills spears that have emerged from the soil, making them worthless, and slows the development of new spears, delaying future production for several days. As a result, the season's output is reduced by more than the amount of the frost-damage spears.

Growers in Michigan can lose up to 40 percent of their crop if they experience several frosts during the same season, although a 10-20 percent loss is more typical (Myers, Neibauer, Zandstra). Michigan growers usually take 15-25 cuttings during a 6-week harvest season. Growers estimate that they typically lose 2-3 of these cuttings following a spring frost.

The location of the field is important in assessing the risk of frost damage. Low-lyin areas are more frost-prone (they are more likely to develop "frost pockets") than highe elevations, and asparagus planted in such fields is likely to suffer larger yield losse than asparagus planted at higher elevations. On higher fields, cold air tends to flow to lower elevations on cold nights.

Extended Cool Weather

Cool weather slows down the asparagus plant's physiology and reduces the number of spears that reach marketable size during the harvest period. However, cool weather is not generally perceived as a major peril. It would not be likely to cause an asparagus yield loss sufficient to result in a crop insurance claim.

Extreme Heat

Excessive heat during the harvest season speeds-up the pace of spear development, thereby disrupting the steady harvesting schedule. Heat speeds the rate of spear growt and makes it hard for growers to harvest as fast as needed to realize maximum yield. I addition, if day-time temperatures are in the 85°-90° F range for a week or more, the plants branch out (develop side shoots) before the spears are long enough to harvest.

Drought

Asparagus is a relatively drought-resistant plant, with roots that can reach a depth of 15-20 feet in sandy soils. However, extreme drought can reduce the current year's yield. It can also reduce the amount of energy stored by the plant during fern growth, reducing the subsequent year's yield. Because asparagus in California and Washington i grown on irrigated land, drought is not considered a production peril in those states. However, drought can reduce yields in the Midwest and in Eastern states.

Some disagreement exists among industry experts as to the severity of drought as a production peril. For example, ASCS contacts in Michigan indicated that drought was th cause of asparagus ad hoc disaster payments made in Oceana and Van Buren counties durin 1988, the year with the largest payments over the 1988-93 period (Garcia, Gavrin). However, extension horticulturalists at Michigan State University were dubious that the reduction in the current year's yield would approach the 40 percent needed in order to have collected disaster payments in that year (Myers, Neibauer, Zandstra).

Excess Moisture

Excess moisture can be a serious production problem if the planting is not on a sufficiently well-drained soil. Asparagus roots cannot tolerate being submerged for extended periods of time without killing the plant. Excess moisture can also lead to root rots and other diseases.

Hail

The occurrence of hail during the harvest season can damage the tender, unharvested spears, scarring them and making them unmarketable for either fresh or processing uses. Yield loss due to hail would probably be limited to less than 15 percent of the normal harvest because the damage is limited to just those spears which have emerged. A growe would not likely lose more than two-to-three cuttings out of an eight-week season to hail damage.

Insects

Asparagus beetles and cutworms are the most widespread insects affecting asparagus production. Other asparagus insects include asparagus aphids, symphylans (garden centipedes), and wireworms.

<u>Asparaqus beetles</u>. There are several species of asparagus beetle, but the "common" asparagus beetle causes the most serious problems. The common asparagus beetle lays it eggs in the spring on spears or ferns. The presence of eggs, larvae, or larval feeding injury on spears is considered a contaminant and results in the affected spears being culled. Harvesting on a timely basis and preventing over-maturity are the best control measures (Cantaluppi).

Larvae feeding on the fern can seriously injure newly-established beds and reduce the vigor of established stands. The beetle can be controlled during the fern stage with insecticide sprays.

<u>Cutworms</u>. As with the asparagus beetle, there are several types of cutworms. Cutworms may injure the asparagus spears by feeding on the tips or they may injure the side of the spear by feeding at or just below the soil line, sometimes severing it completely. Cutworm feeding causes distorted and twisted spear growth.

Some evidence suggests an association between weeds in the asparagus field and cutworm infestations. This is an additional reason for weed control (Dean).

<u>Asparaqus aphids</u>. Asparagus aphid infestations result in marked stunting of fern growth. The greatest damage occurs to young plants. Seedlings and 1-year-old plants may be killed by infestations. Older plants show a range of responses, from moderate weakening of the plants to essentially no effect.

The asparagus aphid has a large number of natural enemies. Ladybird beetles, parasitic wasps, syrphid larvae, and lacewing larvae feed on colonies of asparagus aphids. The likelihood of natural enemies providing adequate protection to prevent aphid toxin from harming the plant, however, is unlikely. The best protection against the asparagus aphid is the use of chemical pesticides.

<u>Symphylans</u>. Symphylans are small, white, centipede-like animals with nocturnal (nighttime) habits. They feed on asparagus roots, sometimes devouring small roots entirely and puncturing holes in larger roots. Infestations generally are associated with heavy (silt or loam) soils. Cultivation to dry out the surface soil of beds may reduce injur to the plants by driving the insects deeper into the soil (Sims, et. al.).

Thrips. Thrip infestations can cause damage to young nurseries, direct-seeded new plantings, seedling-transplanted fields, and new 1-year-old crown plantations. Thrips remove moisture form the fern, weaken its vigor, and can kill the tops of small seedlings. Control consists of monitoring the thrip populations and the use of pesticides (Sims, et. al.).

Diseases

The most serious asparagus diseases are asparagus rust, fusarium wilt, and fusarium crown rot. Stemphylium purple spot, a fungus disease, and several viruses are also production perils for asparagus.

<u>Asparaqus rust</u>. Asparagus rust, a fungus disease, reduces plant vigor and causes ferns to age prematurely, reducing storage reserves in the crown and thereby lowering yields the following season. Asparagus rust is serious in humid areas, especially during year having excessive rainfall.

Asparagus beds should not be planted in areas with poor air drainage or where dew occur frequently, since moisture on the plant's foliage encourages rust development. Preventing growth of volunteer plants during the cutting season and isolating seedling beds from commercial fields also helps in the control of rust. Varieties that are resistant or moderately-resistant retard rust development, and include Delmonte 361, Jersey Giant, Jersey Centennial, and UC 157. Fungicide applications may be necessary t prevent the disease from becoming established in the field (Dean).

Fusarium wilt and Fusarium crown rot. Fusarium wilt and fusarium crown rot are widespread problems that cause premature decline of asparagus stands. Plant stress, other virus infections, high soil temperature, and light soils increase the incidence o disease. Common causes of plant stress include over-cutting, drought, over-watering, insect injury, inadequate weed management, and soil compaction.

Control measures consist of treating seed before planting and not planting asparagus in old beds which are infected with the Fusarium disease. Care during tillage to avoid wounding fleshy roots and crowns helps eliminate avenues for infection.

<u>Stemphylium Purple Spot</u>. Stemphylium purple spot is a fungus that sometimes causes small, slightly-sunken spots on asparagus spears just prior to harvest. The fungus needs moist conditions from dew, rain, or sprinkler irrigation to infect plants. Symptoms are most severe during the early part of the harvest season following wet weather and cool temperatures, and disappear when rainfall ceases and temperatures warm

Control consists of destroying overwintering sources of inoculum such as old, infected ferns and plant debris. Planting cover crops that reduce windblown sand may also aid i disease control

<u>Viruses</u>.

Three viruses--the tobacco streak virus, asparagus virus-1 and asparagus virus-2-represent production perils in growing asparagus. Alone, each of these can reduce vigo or productivity. In certain combinations (such as asparagus virus-1 and asparagus virus-2), however, they cause plants to decline or die, diminishing the stand and lowering yields.

Careful attention to weed (including volunteer asparagus) and insect control helps in the control of viruses. Using seed with a low incidence of the asparagus virus-2 also helps in reducing plantation decline.

Weeds

Weeds (including volunteer asparagus) compete with asparagus for water, nutrients, and light and interfere with harvest efficiency. Weeds also serve as a host for insects an diseases.

Weed control consists of careful attention to cultivation. Herbicide sprays also are available for weed control.

State Analyses

Although there are similarities among areas in the way asparagus is grown, each area ha unique production practices and confronts a unique set of perils. The following sectio analyzes the production practices and perils specific to the major asparagus-growing regions, and examines the potential demand for an asparagus insurance policy.

California

California is the nation's leading state in asparagus production, and accounts for over 40 percent of U.S. asparagus output. California harvested 34,500 acres of asparagus in 1993, and produced 932,000 hundredweight at a total value of \$84 million. Asparagus is grown over a wide range of climatic zones in California, from cool coastal areas to extremely hot desert climates (see Appendix table 5 and the Appendix map).

Average yields vary substantially from area to area within California (Appendix table 5). The highest average yields are reported in Monterey county, where cooler summer temperatures and a long growing season permit a long harvesting period. The Monterey production area also has more virgin soils (soils on which asparagus has not previously been grown) on which to grow asparagus than the Delta area. Soils on which asparagus has previously been grown can be infected with diseases, and plantings on such soils never reach the same productivity as asparagus planted on virgin soil.

At the present, California's asparagus is marketed almost exclusively to the fresh market (California Asparagus Commission). Prior to 1980, however, about half of the asparagus produced in California was canned or frozen (French and Willett). Processing has declined in California since 1980 and the Northwest (primarily Washington state) ha replaced California as the dominant processing region.

Production Perils

The principal weather-related production perils in California include spring frost, excessive rains, unusually high temperature during the harvest period, and excessive wind.

<u>Weather-related</u>. Spring frost is the major risk to asparagus production in California (DePaoli). Frost usually causes a 3- or 4-day loss in the harvesting schedule. If freezing temperatures are persistent, more days may be lost (Bacchetti).

Excessive rain during harvest-time may encourage disease development. Diseases such as phytophthora rot (spear slime) and crown rot are usually caused by over-irrigation or

excessive rainfall. Rain during harvest-time also delays harvesting and could result i partial losses due to branching.

Excessive wind may cause curvature of the spears (University of California, 1993). Asparagus which is badly crooked is marked with the designation "crooks" by the California Food and Agricultural Codes (Federal-State Marketing News Service). Crooked asparagus is of substantially lower market value.

<u>Diseases</u>. Fusarium wilt is the most serious asparagus disease in California (Bacchetti). No production area of California is immune from fusarium wilt.

Phytophthora crown rot also can be potentially damaging if it affects the plant during the harvest season (Channey). Phytophthora is aggravated by exceptionally wet winters. It can be controlled through the application of fungicides in mid-winter, ahead of the harvest season.

Asparagus rust is most prevalent in the damp coastal areas of California, but may also cause problems in humid inland areas. Prevention consists of well-spaced irrigation use, wide row spacings, and orientation of the planting with the prevailing wind direction. Several fungicides are effective at preventing the development of rust in California.

<u>Insects</u>. The main pest problems affecting California asparagus include asparagus aphids, garden centipedes, thrips, asparagus beetles, and cicadas. A serious aphid infestation occurred in Riverside county during 1988 and 1989, destroying as much as 85 percent of the county's asparagus crop. A number of farmers switched out of asparagus production following that incident and Riverside's production never fully recovered, remaining at about 15 percent of the pre-infestation level (Chanla).

Asparagus beetles, although found wherever asparagus is grown, are usually not a seriou pest in California.

The garden centipede is chiefly a problem with white asparagus in California. As California has cut back its white asparagus production, the importance of this pest has declined.

Although some cicada infestations have occurred, the extent to which they damage the asparagus crop appears to be limited to minimal feeding on the roots while the nymphs are in the soil.

Harvesting Dates

The peak harvest season in California is March through the early part of June. Althoug a small amount of asparagus is harvested in the fall in the Imperial and Central valleys, fall harvest is a very small part of California's production. The following harvest dates apply to the various areas of California:

Producing regions	Harvest period $^{1/}$	Peak harvest
-------------------	------------------------	--------------

Delta, Central San Joaquin area	March 1 - June 20	April
Salinas area (Monterey county)	March 10 - July 15	April, May
Imperial area	Jan. 15 - April 15	Feb., March
Los Angeles and Orange counties	March 1 - June 15	April, May

 $^{\scriptscriptstyle 1/}$ Small quantities are also harvested during August-October in the central San Joaquin and Imperial Valley areas.

Source: California Agricultural Statistics Service.

Sources of Individual Yield Data

The California Asparagus Commission funds its asparagus research and promotion activities on the basis of grower assessments on production (16.5 cents per 30 pound carton). The Commission reports it has production and acreage records for its growers and that individual-grower yield series could be developed from these data (DePaoli).

Demand for Insurance

The demand for an asparagus policy among California growers is likely to be low (DePaoli). The weather-related production perils faced by California asparagus growers do not typically cause significant losses. The most serious peril is early spring frost, which destroys only the spears that have emerged from the ground--usually 2-4 days of cuttings out of an 8-week harvest. Privately-offered commercial crop insurance for asparagus was offered at times in the past, but grower participation was low (DePaoli).

Michigan

Michigan ranks a distant third among asparagus-growing states, after California and Washington. The state accounted for 13 percent of U.S. output in 1993. Michigan harvested 19,000 acres of asparagus in 1993, and produced 285,000 hundredweight at a total value of \$17 million.

The largest number of growers and the majority of Michigan's acreage is located in the west central and southwestern parts of the state in the counties bordering Lake Michigan. Oceana and Mason counties contained the largest acreage in 1992 (Michigan Department of Agriculture). Substantial amounts of asparagus are also grown in Allegan Berrien, Cass, Manistee, Muskegon, Ottawa, and Van Buren counties.

Lake Michigan moderates the effects of the weather, benefitting asparagus production in the adjoining counties. It reduces the incidence of yield-diminishing late frosts and it helps reduce the effects of high temperatures, which can shorten the harvest period. Although the moderating effect declines with distance from the Lake, it is judged to be important in asparagus production at least 20 miles inland (Myers).

The Census of Agriculture reported 881 farms in Michigan with asparagus sales in 1987. The Michigan Department of Agriculture, however, reported only 580 growers in 1992 (Michigan Department of Agriculture).

The average size of Michigan asparagus operation in 1992 was 34 acres (Michigan Department of Agriculture). The average processing asparagus acreage was 47 acres, compared with 9 acres for fresh-market acreage. Some growers marketed both fresh and processing asparagus. Asparagus growers in the west central production area tend to have larger operations than in southwest Michigan.

The county extension agent in Oceana county in west central Michigan, the major asparagus-growing county in Michigan, indicated that asparagus operations in his county ranged from a couple of acres to about 1,000 acres (Myers). He said farmers in his are with 50 or more acres of asparagus probably represented the most efficient operations.

Eighty-nine percent of Michigan's asparagus production was for processing in 1992 and 1 percent for the fresh market. The largest amount of processing asparagus in Michigan i used for canning--only a small fraction is frozen (Neibauer).

Asparagus yields in Michigan depend on the age of the planting. New plantations are planted to hybrids, which are higher-yielding than the older varieties. Mary Washington, the principal older variety, accounted for 38 percent of Michigan's

asparagus acreage in 1992. Jersey Giant, Jersey Knight, and Syn 4-56 are three of the leading new varieties. Jersey Giant and Jersey Knight are all-male varieties; not all of the new plantings, however, are of the all-male type.

Asparagus tends to be the main business for growers in the west central area (Myers). Typically, asparagus growers in the west central counties also produce fruits (cherries and, to a lesser extent, apples and peaches) and in some cases, vegetables, such as zucchini, peppers, and snap beans. Asparagus operations are smaller in the southwest and are usually grown in combination with other vegetables and, in some cases, fruits.

Production Perils

Late spring frost is the major production peril for asparagus in Michigan. Other peril are extreme heat, excessive moisture, drought, insects, and diseases (Garcia, Gavrin, Neibauer, Zandstra).

<u>Weather-related</u>. Michigan growers take 15-25 cuttings during a 6-week harvest season and estimate that they lose 2-3 of these cuttings following a spring frost.

One specialist said that there were more damaging spring frosts in the southwest Michigan production area in 1994 than in any other year he could remember. He judged that yields may have been reduced on some low-lying asparagus fields by as much as 40 percent, while on higher fields with better air drainage, yields may have been reduced by only 10 percent (Zandstra).

Extreme heat toward the end of the cutting season occasionally reduces yields in Michigan, although this peril is not considered a serious production risk.

Drought is also a production peril in Michigan. ASCS county offices indicated that the disaster payments made for asparagus in Oceana and Van Buren counties during 1988 were the result of drought-caused losses.

Excessive moisture. Excessive rainfall does not generally reduce current-season asparagus yields in Michigan. Asparagus is planted on relatively well- drained, sandy soils which are able to dissipate excessive rain fairly well. However, excessive rainfall can cause immediate yield losses if the asparagus is plante on poorly-drained soils. Asparagus roots, like those of many other plants, need free oxygen for respiration, and will die if deprived of air for very long.

The main problem associated with excessive rain occurs in future seasons. An excessively wet season can result in a high incidence of asparagus rust, which reduces the yield in the subsequent season. Excessive soil moisture also promotes the development of fusarium root rot, which cause the plantation to decline (the plants die at an early age (Myers, Zandstra).

<u>Hail</u>. Hail can cause the loss of one to two cuttings because it damages spears which have broken through the soil, making them unmarketable. Hail damage, however, is not a important source of yield loss for asparagus in Michigan (Myers, Zandstra).

<u>Insects and disease</u>. Insects, such as the asparagus beetle and cutworms, are productio perils for Michigan asparagus, but losses are generally preventable if the grower

follows recommended production practices. The major disease problems are fusarium crow rot and asparagus rust.

Demand for Insurance

The demand for asparagus crop insurance among Michigan growers is likely to be fairly low because the production perils they face do not generally cause total crop losses over the season (Kelly, Foster). The production risks that exist (primarily late sprin frost) result in the loss of only a portion of the crop. Hail is a production risk in Michigan, but asparagus growers do not generally buy hail insurance.

Sources of yield data

The Michigan Asparagus Advisory Board funds research and promotion activities for Michigan asparagus through assessments on its growers based on production. However, th Advisory Board does not have a corresponding record of acreage which could be used to compute yields (Foster).

New Jersey

New Jersey produced 23,000 hundredweight of asparagus in 1993, about 1 percent of U.S. production. Asparagus operations in New Jersey are concentrated in Gloucester and Sale counties in the southwestern part of the State. Some plantings are also located in Burlington county, with the remainder scattered throughout the state. Asparagus in New Jersey is grown mainly on fine, sandy loam soils. All of the New Jersey asparagus crop is sold for the fresh market, with a significant portion sold through roadside markets.

The Census of Agriculture reported 179 farms in New Jersey with asparagus in 1987. An extension horticulturalist at Rutgers estimates there are over 100 farms remaining toda (Garrison). Most growers have one to two acres of asparagus. About 900 acres of asparagus were harvested in the state in 1993 (USDA, NASS). Virtually all new planting in New Jersey are with the all-male hybrids developed by the Rutgers Experiment Station

Most New Jersey growers produce crops other than asparagus, including other vegetable crops. Consequently, they typically have irrigation equipment available. However, asparagus is generally irrigated in New Jersey only during the first two years of growth, when the crop is becoming established.

The harvest season lasts six to eight weeks, from mid-April to mid-June. Growers may harvest every other day during periods with cool temperatures, and as often as twice a day during periods with unusually warm temperatures. On average, asparagus in New Jersey is harvested about 5 times a week.

Production Perils

The major peril to asparagus production in New Jersey is frost and freeze damage. Othe perils include hail, drought, and excessive wind.

<u>Weather-related</u>. The major New Jersey peril is frost and freeze damage during harvest, usually limited to the first two weeks of the harvest season. Typically, 3-7 days of harvesting will be lost to freeze damage (Garrison).

Hail damage is also a peril. Hail during the harvest season can cause the loss of several days of harvesting. In addition, hail during fern growth in July and August (the re-establishment period) can reduce the next year's yield by up to 50 percent.

Drought during the re-establishment period can also reduce the subsequent season's yield. Drought during the harvest period is generally not a problem because New Jersey typically gets adequate rainfall at that time. Excess moisture is not a production peril in New Jersey, except in low-lying areas.

Excessive wind can reduce yields if blowing sand damages the tender spears. Sanddamaged spears develop a crooked shape and have little or no market value. Excessive wind can also break off asparagus stalks during the re-establishment period, reducing the plant's energy buildup and lowering the yield in the subsequent season.

<u>Insects and diseases</u>. Various insects and diseases are production perils in New Jersey but they can generally be controlled with recommended management practices. One particular problem, however, is asparagus rust. This disease is promoted by excessive dew or mist between mid-August and mid-September, and results in reduced yields the following year.

Illinois

Illinois produced 11,000 cwt of asparagus in 1993, about 0.5 percent of U.S. asparagus output. The Census of Agriculture reported 62 farms in Illinois with asparagus sales i 1987. The average size of most Illinois asparagus operations is one to two acres (Cantaluppi). There are some larger operations, mostly located in northern Illinois.

Asparagus production in Illinois is located around population centers and most is sold locally for the fresh market. Many growers sell their production through roadside stands, farmers' markets, and pick-your-own. There is also a processing plant at Princeville in northern Illinois which buys asparagus.

Harvesting typically starts about April 20 and lasts through early June. Most harvesting is done by hand with the picker walking through the field. Some operations, usually those larger than one acre, use a picking aid on which the worker lies on his o her stomach and snaps off the harvestable spears as the machine moves down the row.

<u>Production Perils</u>. The major peril in Illinois is late spring frost. Other perils include excess moisture, drought, and hail.

<u>Weather-related</u>. The major production peril affecting asparagus production in Illinois is spring frost. Frost kills the spears which have emerged but also slows future production for several days. Consequently, production is reduced by more than the amount of the frost-damaged spears.

Excess moisture can be a serious production problem if the planting is not on a sufficiently well-drained soil. Asparagus cannot tolerate being submerged for extended periods of time without killing the plant. Excess moisture can also lead to root rots.

Drought and hail are also production perils. Asparagus is relatively drought- tolerant but extended dry weather during fern growth reduces the amount of energy re-stored to the roots and diminishes the yield during the subsequent year.

<u>Insects and diseases</u>. Various insects and diseases are production perils in Illinois, but they can generally be controlled with recommended management practices.

Washington

Washington accounted for about 30 percent of U.S. asparagus acreage and 40 percent of U.S. production in 1993 (USDA, NASS). USDA reported 25,500 harvested acres in Washington in 1993, down from 32,000 in 1989. The decline in acreage was somewhat larger than the rise in average yield over this period, and production declined by more than 10 percent. Washington produced 89 million pounds of asparagus in 1993 with an average farm value of \$55 million.

Washington's asparagus is located in the Yakima and Columbia River valleys in south central Washington. Franklin and Yakima are the major producing counties, accounting for about three-quarters of Washington's total output. Other asparagus-producing counties reported by the Washington Department of Agriculture are Adams, Benton, Grant, and Walla Walla counties.

The Census of Agriculture reported 483 farms growing asparagus in Washington in 1987. The Washington Asparagus Commission reported 380-400 members in 1994 (Webring). Asparagus operations range in size from less than an acre to several hundred acres (Folwell).

Washington grows asparagus primarily for processing use. An estimated 70 percent of th crop is sold for processing use, with the remaining 30 percent destined for the fresh market.

The harvest period in Washington is about eight weeks, running from late April to about June 20. Asparagus is cut about every three days early in the season when the weather is cool and the spears are growing slowly. As the ground warms up later in the season and spear growth accelerates, asparagus may be cut daily.

Production Perils

As in other states, the major peril to asparagus production in Washington is spring frost. Other perils include excessive wind and hail.

<u>Weather-related</u>. The major weather-related production peril is late spring frost. Other weather perils are excessive wind and hail (Van Denburgh). Excessive wind is a peril when asparagus is planted on sandy soils, which are found mainly in lower Yakima county and the Columbia Basin in Washington. Wind-blown sand injures the asparagus spear on its windward side, causing it to grow crooked rather than straight. There is no market for crooked asparagus.

Damage from frost, excessive wind, or hail are not likely to reduce asparagus yields enough in Washington to qualify a grower for an insurance indemnity. Yields losses fro any of these risks are estimated to typically be in the 5- to 10- percent range. <u>Insects and diseases</u>. Uncontrolled insect infestations, diseases and excessive weed growth also are production perils in Washington. All of these, however, are risks over which the grower has a great deal of control.

Demand for Insurance

The demand for a potential asparagus policy in Washington is likely to be low because damage from weather-related perils typically does not cause losses of such magnitude that a grower would quality for an indemnity payment. Weather perils usually damage only that portion of the crop that has already emerged from the ground, but that has no yet been harvested (about two- to three-day's growth). Consequently, the loss consists only of a two- or three-day yield out of an eight-week harvest season.

Some production perils, such as uncontrolled weeds growth, diseases, and viruses, can result in early decline or complete loss of the plantation. However, growers generally have a great deal of control over these perils. The director of communications for the Washington Asparagus Commission indicated that crop insurance has not been an issue which the commission has discussed in recent years (Webring).

Sources of Yield Data

There are two asparagus organizations in Washington. The Washington Asparagus Commission funds asparagus promotion and production and marketing research and represents the interests of Washington asparagus growers. The commission's activities are supported by assessments on all growers based on the amount of production. An estimate of a grower's production could be made from assessments, but there is no recor of acreage associated with the production from which yields could be estimated (Webring).

The Washington-Oregon Asparagus Growers Association is a grower bargaining cooperative which negotiates with processors for the prices paid for processing asparagus. The association represented 155 growers in 1994. There are five processors in Washington, but not all of the processors negotiate with the association (Folwell). At least one processor, Green Giant, does not purchase its asparagus through the association. The Washington-Oregon Asparagus Growers Association keeps records on members' production, but does not record the acreage from which the production was harvested.

Ad Hoc Disaster Assistance for Asparagus

Ad hoc disaster assistance legislation was made available for losses of commercially-grown crops in each of the years 1988-93. Ad hoc payments provide an indication of high-loss areas during that period, and may indicate states and counties that would face relatively high risk under a potential FCIC asparagus policy. These data may also suggest the areas where the demand for an asparagus crop insurance policy would be relatively high.

Under the 1988-93 legislation, payments were made under the categories of participating program crops, nonparticipating program crops, sugar, tobacco, peanuts, soybeans, sunflowers, nonprogram crops, ornamentals, and at times, aquaculture. Producers without crop insurance--the case for asparagus--were

eligible for payments for losses greater than 40 percent of expected production. If a producer had no individual yield data to use in calculating "expected production," county-level or other data were used as a proxy. Payment rates for asparagus were based on 65 percent of a 5-year average price, dropping the high and low years.

Disaster assistance payments for asparagus (fresh and processed) totalled \$2.5 million over the 1988-93 period. Payments for fresh asparagus accounted for 65 percent of the total and payments for processed asparagus accounted for 35 percent. Payments for total (fresh and processed) asparagus losses peaked at \$1.05 million in 1988, and were over \$325,000 in 1989 and 1993. Payments made for asparagus accounted for about 0.06 percent of all ad hoc assistance for non-program crops (that is, non-price and income support crops) over the 1988-93 period.

Ad hoc disaster payments for asparagus were scattered over a geographically broad area. For fresh asparagus, 27 states received payments in at least one of the six years, with 6 states collecting payments in all years. For processed asparagus, 5 states collected payments in one of the 6 years, with Michigan and Oklahoma receiving payments in all years. Payments for asparagus were reported in a variety of states for which NASS does not collect asparagus statistics--including Missouri, Oklahoma, and Virginia. In an ordering of counties, Morrison county, Minnesota ranked first in fresh asparagus payments, receiving \$140,000 over the 6-year period. The next three states in the series include: Grant county, Washington (\$127,000); Saline county, Missouri (\$106,188); and Kern county, California (\$86,624). A total of 207 counties received payments in at least one of the 6 years for fresh asparagus yield losses.

For processed asparagus, the top-ranked counties in ad hoc payments include the Michigan counties of: Van Buren (\$196,238); Oceana (\$122,306); Manistee (\$109,154); and Berrien (\$66,449). Of the ten top-ranked counties, eight were located in Michigan and two in Washington. A total of 27 counties received payments in at least one of the 6 years for processed asparagus losses.

Ad hoc disaster data can be used to indicate which asparagus-producing areas received large payments relative to their acreage (Table 11). Michigan accounted for an average 23.6 percent of asparagus harvested acreage over the 1988-93 period, and received 35.5 percent of ad hoc asparagus payments. Similarly, Illinois accounted for 0.9 percent of U.S. asparagus acreage between 1988 and 1993, and received over 4 percent of the payments made for that crop.

In contrast, California and Washington collected smaller shares of ad hoc payments relative to their acreage. California accounted for 39 percent of asparagus acreage and 3.5 percent of payments, while Washington accounted for 32 percent of U.S. acreage and 12 percent of payments.

Disaster payments for the five NASS asparagus states averaged 0.2 percent of the total U.S. asparagus crop value over the six years (Table 12). Disaster payments as a percent of crop value were highest in Illinois (2 percent) and lowest in California and Washington (less than 0.05 percent). The low payments in California and Washington reflect the relative absence of weatherrelated production perils in these States. All of California's and Washington's asparagus is irrigated so drought is not a production peril. In addition, spring temperatures may be less variable (less chance of a frost once asparagus harvest has begun) in California and Washington than in Michigan and Illinois.

Asparagus Insurance Implementation Issues

Adverse Selection and Multiple-Year Insurance

If FCIC decides to offer crop insurance for asparagus, it may be necessary to offer a multiple-year policy. A number of asparagus production perils have little or no effect on the current season's yield, but can cause substantial yield loss in subsequent years. Extreme drought, severe hail damage to the fern growth, stalk breakage due to excessive wind, and disease buildup, for example, may not reduce the current seasons's yield, but they disrupt the plant's energy build-up during fern growth and can substantially reduce yield during subsequent harvests. In order to avoid adverse selection--growers taking out insurance after an event occurred that reduced future yield

State	Average asparagus harvested acreage, 1988-93	Share of U.S. acreage	Total asparagus disaster payments, 1988-93	Share of U.S. asparagus disaster payments
	Acres	Percent	Thousand Dollars	Percent
California	35,917	38.7	87.8	3.5
Illinois	793	0.9	105.4	4.3

prospects--it may be necessary to require that growers insure for a period of years.

A minimum step in reducing adverse selection would be to define the crop year as beginning with the fern growth in one year and extending through the conclusion of harvest the following year (perhaps July 1 through June 30 in Washington and Michigan). Defining the crop season in this way would help rule out adverse selection for some perils, but not all. Because asparagus is a perennial crop, the yield-reducing effects of an adverse event can extend over several seasons, and sometimes for the life of the plantation.

Setting Reference Prices

FCIC provides a reference price (price election) for the insured crop which becomes the basis for assigning value to yield losses. The insured grower elects a price guarantee, normally between 30 and 100 percent of the reference price.

A reference price for asparagus probably should represent the in-field value of the crop, because growers would generally not incur the expenses for harvesting and marketing on that portion of the yield that was lost. Variable harvesting and marketing expenses account for a relatively large share of total costs for asparagus (perhaps as much as 75 percent for fresh asparagus and 25-50 percent for processing asparagus). Using a fresh-market f.o.b. price or a season average price for processing asparagus could create the situation where growers would realize a higher return from indemnity payments than the market value of the crop. Such a situation would provide undue incentive for moral hazard.

There are two approaches to arrive at an "in-field" reference price. One is to deduct the estimated harvesting costs from a market price. The second is to estimate the cost of production and use it as a proxy for the in-field price. The market price here refers to the grower price and not the retail price.

Actual Production History (APH) and Plantation Maturity

A complicating factor in determining a producer's APH is that yields vary with the age of the plantation. Yields usually rise during the first 2 or 3 harvest years as the plantation matures. This stage is followed by several years of a yield plateau and then several years of declining yields until the production no longer justifies the cost for maintaining the plantation and harvesting the asparagus. Consequently, the age of the plantation needs to be taken into account in developing an average yield.

The "rule of thumb" used by the California Asparagus Commission to project production on the basis of the age distribution of plantings illustrates the relationship between yield and age of planting. The commission uses 600 pounds per acre for the first harvest year, 3,100 pound for the 2nd through 6th year, 2,300 pounds for the 7th through the 9th year and 1,620 pounds harvests after the 9th year (DePaoli). This schedule of yield-age relationship would be different for individual growers because of soil, climate, and management differences.

Another complicating factor in determining actual production history is that yields for the new "all-male" varieties average higher than for the older open-pollinated varieties. Most new asparagus plantations are planted with the newer hybrid varieties. APH yields for plantings of the open-pollinated varieties would need to be discounted from the average for the newer hybrids.

Because of the bearing pattern of asparagus and the fact that new varieties have substantially higher expected yields, an APH in which past years are averaged to obtain an expected yield may have to be adjusted for plantation age and plant variety. An alternative to using an average APH for the plantation may be to offer separate policies based on: 1) the establishment years, 2) prime-production years, and 3) declining years, each with different rates and coverages.

Estimating "Appraised Production"

Estimating appraised production for asparagus (harvestable, but unharvested yield) would require taking into account not only the age of the plantation (see the "Actual Production History and Plantation Maturity" section), but also the number of cuttings already taken or the number of cutting days remaining in the season.

An appropriate formula for estimating unharvested yield would be: APH multiplied by a "remaining-season" adjustment. A gross remaining-season adjustment would be the percentage of the normal harvest season remaining when cutting ceased. This factor would tend to over estimate appraised production, however, because yield per day usually declines as the season comes to an end. A refinement to the remaining-season adjustment would account for the higher yields per day at the beginning of the season.

Insuring Price Risk

There would likely be less interest among asparagus growers in a revenue insurance policy than among growers of most other perishable commodities. Price variability during most seasons appears to be less of a risk in asparagus growing than for other perishable vegetables such as lettuce. Most of the asparagus crop is harvested during April and May when prices are relatively stable from year-to-year compared with prices for other fresh vegetables. The reason for this relative stability is that asparagus can be diverted between fresh and processing uses, and the processing price more or less acts as a floor for the fresh price during the peak harvest (see the "Prices" section). Processing asparagus prices, on the other hand, are arrived at through pre-season bargaining and remain relative stable within the season.

Market Prices and Moral Hazard

Low market prices are not as likely to be an incentive for moral hazard with an asparagus insurance policy as with some other perishable vegetables because asparagus prices tend to be more predictable than prices for vegetables such as celery and lettuce. In addition, growers have less flexibility in neglecting an asparagus crop than with celery and lettuce.

Availability of Individual Yield Data

Individual acreage and production data are available for California growers through the California Asparagus Commission. The availability of individual yield data appears to be less readily available in Washington and Michigan. Although the grower associations in Washington and Michigan fund their research and promotion activities on the basis of grower assessments on production, they do not maintain records of the acreage which would be needed to calculate individual grower's yields.

Demand for Insurance

Our assessment is that asparagus does not seem like a very good candidate for insurance relative to the other specialty crops we have examined. There is not likely to be very much demand for multiple-peril insurance by asparagus growers, especially in the two largest production areas (California and Washington), because growers do not face production perils that result in the loss of a large portion of their yield. Disaster assistance payments to asparagus growers in the nine USDA-reported states amount to only 0.2 percent of the value of crop, compared to 2.4-6.6 percent for major field crops (Table 13).

The largest potential demand is likely to occur in Michigan and other midwestern and eastern areas because weather-related yield losses appear to be more frequent in these areas than in the western states. Despite the relatively larger losses in the eastern and midwestern states, it does not appear that crop insurance would be an important risk-management tool for growers in these states because production losses due to weather causes account for a relatively small share of grower returns. In Michigan, for example, disaster assistance payments between 1988 and 1993 averaged only 1 percent of the value of the asparagus crop (see Table 12).

A further indicator of the potential demand for an asparagus policy derives from FCIC records on requests for insurance. Unlike the other specialty crops we have examined, these records indicate that FCIC has received no requests for an asparagus policy since 1990.

Crop	Disaster payments	Crop insurance payments	Total	1992 crop insurance participation
	Perce	ent of crop value		Percent
Corn	1.7	1.2	2.9	29
Soybeans	1.4	1.0	2.4	24
Wheat	3.3	3.3	6.6	41
Asparagus	0.2	NA	0.2	NA
